Practical Task 1

Introduction:

The task required creating a Python script that interacts with the user by taking their name and age as input and then printing these values along with the string "Hello World!". This involves understanding basic Python syntax, user input/output, and string manipulation.

Breakdown:

The task was broken down into three main parts. The first part involved taking the user's name as input and printing it. The second part involved taking the user's age as input and printing it. Finally, the third part requires a script to print "Hello World!".

Part 1:

In the first part of the solution, we used the `input()` function to prompt the user to enter their name. This function waits for the user to type some input and press enter. The input provided by the user is always a string. We stored this input in a variable called `name`. Then, we used the `print()` function to print the user's name. The `print()` function outputs its arguments to the console.

Part 2:

In the second part of the solution, we followed a similar approach to take the user's age as input. We used the `input()` function again to prompt the user to enter their age and stored this input in a variable called `age`. Then, we used the `print()` function to print the user's age. Finally, we used the `print()` function one more time to print "Hello World!".

Part 3:

In the third part we used the `print()` function one more time to print "Hello World!".

Conclusion:

This solution demonstrates basic user interaction in Python. It shows how to take user input, store it in variables, and print it. It also shows how to print a string. The key functions used in this solution are `input()` and `print()`, which are fundamental for user interaction in Python. However, it's important to note that the `input()` function always returns a string, so if you need a number, you'll have to convert the input to the appropriate numeric type. Also, be aware that the `input()` function will block the execution of your program until the user provides input, so it's not suitable for applications where you need to do other things at the same time.

Practical Task 2

Introduction:

The task was to create a Python script that declares certain variables, converts them to different data types, and then prints these variables. This involves understanding basic Python syntax, variable declaration, type conversion, and user output.

Breakdown:

The task was broken down into three main parts. The first part involved declaring the variables `num1`, `num2`, `num3`, and `string1` with their initial values. The second part involved converting these variables to different data types. The third part involved printing these variables.

Part 1:

In the first part of the solution, we declared the variables `num1`, `num2`, `num3`, and `string1` with their initial values. We used the assignment operator `=` to assign the values to the variables.

Part 2:

In the second part of the solution, we converted the variables to different data types. We used the `int()` function to convert `num1` to an integer, the `float()` function

to convert `num2` to a float, the `str()` function to convert `num3` to a string, and the `int()` function to convert `string1` to an integer.

Part 3:

In the third part of the solution, we printed the variables using the `print()` function. This function outputs its arguments to the console. We also printed the data types of the variables using the `type()` function to verify that the conversions were successful.

Conclusion:

This solution demonstrates basic variable manipulation in Python. It shows how to declare variables, convert them to different data types, and print them. The key functions used in this solution are `int()`, `float()`, `str()`, `print()`, and `type()`, which are fundamental for variable manipulation in Python. Also, be aware that the `print()` function automatically inserts a new line at the end, so each variable will be printed on a separate line.
